Presolar silicon carbide grains of type X account for 1% of presolar SiC and, in all likelihood, formed in the ejecta of core-collapse supernovae. This is indicated by, e.g., large overabundances of the (primary) $^{28}\text{Si}$ isotope relative to the (secondary) $^{29}\text{Si}$ and $^{30}\text{Si}$ isotopes, as well as a large abundance of $^{44}\text{Ti}$ at the time of formation, now showing up as the decay product $^{44}\text{Ca}$ (e.g., [1]). More recently, subtypes X0, X1, and X2 have been defined, depending on the detailed position in a Si three-isotope diagram [2]. Here we review available literature data for barium and strontium in X1 and X2 grains [3-5]. Grains of type X2, to first order, are enriched in s-process Ba compared to Solar System Ba. X1 grains contain, in addition, a variable admixture of a component low in $^{135}\text{Ba}$ and $^{136}\text{Ba}$ (relative to solar and $^{137}\text{Ba}$), but high in $^{138}\text{Ba}$. This component may represent r-process Ba or Ba produced by a neutron burst like the one proposed by [6]. The delayed appearance of $^{137}\text{Ba}$ due to the 30 a half-life of its precursor $^{137}\text{Cs}$ may allow to date condensation of X1 grains from supernova ejecta, suggesting 5 a for the case of r-process Ba and 8 a in case of the neutron burst of [6]. The value from the r-process depends sensitively on the r-process production of $^{138}\text{Ba}$, which is, however, highly uncertain because of the predominance of s-process $^{138}\text{Ba}$ in the Solar System abundance distribution. Data for Sr are scarcer and more enigmatic, but, to first order, compatible with the inferences from Ba. X1 grains are rich in $^{88}\text{Sr}$, while the signature in X2 grains is characterized by uniquely low $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (down to 0.4 vs. the normal value of 0.7), possibly indicative of contributions from an s-process that was extremely weak.
